

Cell division

Cell division is an integral part of the cell cycle; it is the process by which a parent cell divides into two or more daughter cells.

- In **unicellular organisms**, the division of one cell reproduces the entire organism.
- **Multicellular organisms** depend on cell division for development from a fertilized cell, growth, and repair.
- Most cell divisions result in daughter cells with identical genetic information, DNA. The exception is meiosis, a special type of division that can produce sperm and egg cells.

Binary Fission in Bacteria

- Prokaryotes (bacteria and archaea) reproduce by a type of cell division called binary fission
- In binary fission, the chromosome replicates, and the two daughter chromosomes actively move apart.
- The plasma membrane pinches inward, dividing the cell into two.

Figure 12.12-4

- **Eukaryotic cell**

Eukaryotic cell division consists of:

- **Mitosis**, the division of the genetic material in the nucleus.
- **Cytokinesis**, the division of the cytoplasm.
- Gametes are produced by a variation of cell division called **meiosis**.
- Meiosis yields **non-identical daughter** cells that have only one set of chromosomes, half as many as the parent cell.

Mitosis.

The part of cell division which results in two identical daughter cells from a single parent cell.

Cell Division can be divided into stages

- Interphase
- Prophase
- Metaphase
- Anaphase
- Telophase
- Cytokinesis

1- Interphase

The cell prepares for division

- DNA replicated (copied)
- Makes new organelles (synthesis)
- Cell increases in size (growth)

2- Prophase

The cell prepares for nuclear division

- Chromosomes appear –
- Centrioles separate & spindles form
- Nuclear envelope disappears
- Longest phase in mitosis.

3- Metaphase:

The cell prepares chromosomes for division.

- Chromosomes line up at the middle of the cell
- Spindle fibers attach to chromosomes at the centromere
- Shortest phase of mitosis

4-Anaphase

- The chromosomes divide
- Spindle fibers pull chromosomes apart
- $\frac{1}{2}$ of each chromosome (called chromatid) moves to poles of cells

5 - Telophase

The cytoplasm divides

- DNA uncoils & appears as chromatin again
- 2 nuclei form
- Cell membrane pinches in to form the 2 new daughter cells

6-Cytokinesis

- Division of the cytoplasm- creating 2 new cells
- Begins in telophase

- Meiosis.

Meiosis is the form of eukaryotic cell division that produces **haploid** sex cells or

- Meiosis.

Meiosis is the form of eukaryotic cell division that produces **haploid** sex cells or gametes (which contain a single copy of each chromosome) from **diploid** cells (which contain two copies of each chromosome). The process takes the form of one DNA replication followed by two successive nuclear and cellular divisions (Meiosis I and Meiosis II). As in mitosis, meiosis is preceded by a process of DNA replication that converts each chromosome into two sister chromatids.

Meiosis I

Meiosis I separates the pairs of homologous chromosomes, a special cell division reduces the cell from diploid to haploid.

1- Prophase I

The homologous chromosomes pair and exchange DNA to form recombinant chromosomes. Prophase I is divided into **five phases**:

- **Leptotene**: Chromosomes start to condense.
- **Zygotene**: Homologous chromosomes become closely associated (synapsis) to form pairs of chromosomes (bivalents) consisting of four chromatids (tetrads).
- **Pachytene**: Crossing over between pairs of homologous chromosomes to form chiasmata.
- **Diplotene**: Homologous chromosomes start to separate but remain attached by chiasmata.
- **Diakinesis**: Homologous chromosomes continue to separate, and chiasmata move to the ends of the chromosomes.

2- Prometaphase I

Spindle apparatus formed and chromosomes attached to spindle fibers by kinetochores.

3- Metaphase I

Homologous pairs of chromosomes (bivalents) arranged as a double row along the metaphase plate.

4- Anaphase I

The homologous chromosomes in each bivalent are separated and move to the opposite poles of the cell.

5- Telophase I

The chromosomes become diffuse and the nuclear membrane reforms.

6- Cytokinesis

The final cellular division to form two new cells, followed by Meiosis II.

Meiosis I is a reduction division: the original diploid cell had two copies of each chromosome; the newly formed haploid cells have one copy of each chromosome.

Meiosis II

- Meiosis II separates each chromosome into two chromatids.
- The events of Meiosis II are analogous to those of a mitotic division, although the number of chromosomes has been halved.
- Meiosis generates **genetic diversity** through the exchange of genetic material between homologous chromosomes during Meiosis I.
